Confidence Intervals and Hypothesis Testing

Confidence Intervals

"Information derived from a sample of observations can only be an approximation of the entire population. To make a definitive statement about an entire population, every member of that population would need to be measured."

Myatt, Glenn J., and Wayne P. Johnson. *Making Sense of Data I: A Practical Guide to Exploratory Data Analysis and Data Mining*, John Wiley & Sons, Incorporated, 2014. *ProQuest Ebook Central*, http://ebookcentral.proquest.com/lib/allegheny-ebooks/detail.action?docID=1729064.

- Not everything can be measured
- We need to make estimates based on existing data
- This leads to ability to say something is "statistically significant"

Sample vs Observation

"Confidence intervals are a measure of our uncertainty about the statistics we calculate from a **single sample** of observations."

- Nb, a sample is a set of observations
- If every possible observation were recorded, we would no longer have a sample, we would have an entire population

 e.g. one sample of 10 humans → 10 weights are observed → single sample mean

Sample vs Population

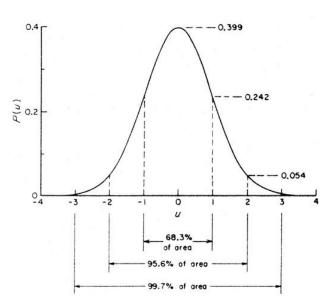

- e.g. one sample of 10 humans → 10 weights are observed → single sample mean
- 10 humans is not the entire population

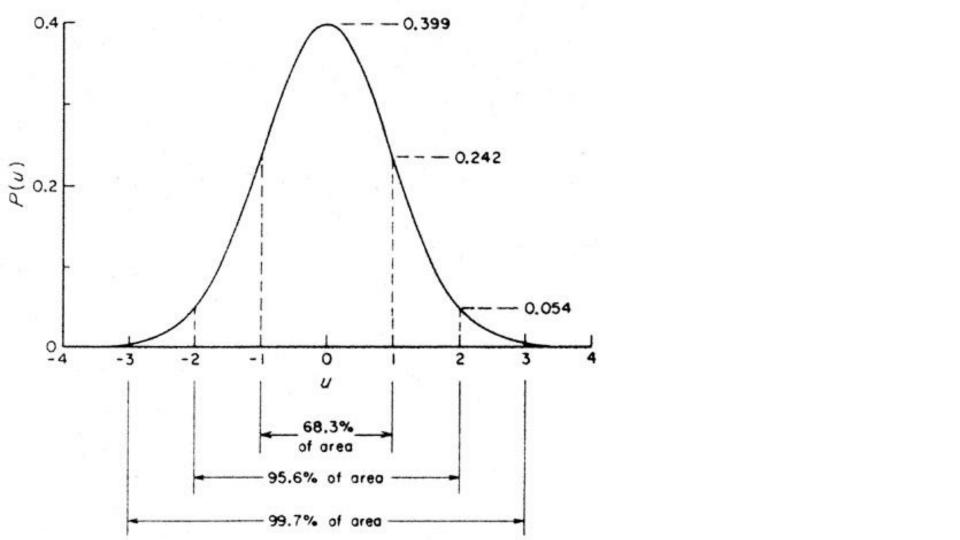

- A different sample would have a slightly different mean
- yet a different sample would have a slightly different mean
- The distribution of means is called the sampling distribution of the mean
- The mean of the sampling distribution is called the **expected value** of the mean
- The standard dev of sampling distribution is the standard error of the mean

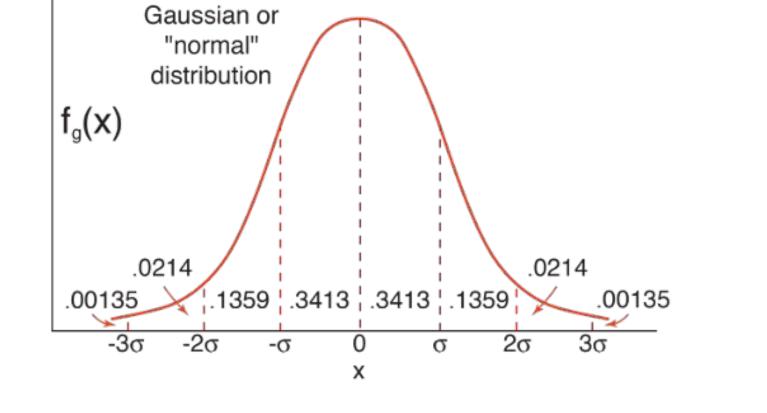

Thanks to the central limit theorem

- sampling distributions are gaussian! (normal, bell)
- the properties of gaussian distributions are very nice
- https://en.wikipedia.org/wiki/68%E2%80%9395%E2%80%9399.7 rule

- The normalized area under the curve is 1
- 95% of the observations fall within ±2 sigma!

Connecting Observations to Populations

Formula for Standard Error of the Mean:

- SEM = SD / \sqrt{n}
 - o SD is standard deviation of a sample
 - o n is number of observations in sample

- For fixed SD
 - o if n is small, SEM is?
 - o if n is large, SEM is?

Connecting Observations to Populations

Formula for Standard Error of the Mean:

- SEM = SD / \sqrt{n}
 - o SD is standard deviation of a sample
 - o n is number of observations in sample

- For fixed SD
 - o if n is small, SEM is large
 - o if n is large, SEM is small

Connecting Observations to Populations

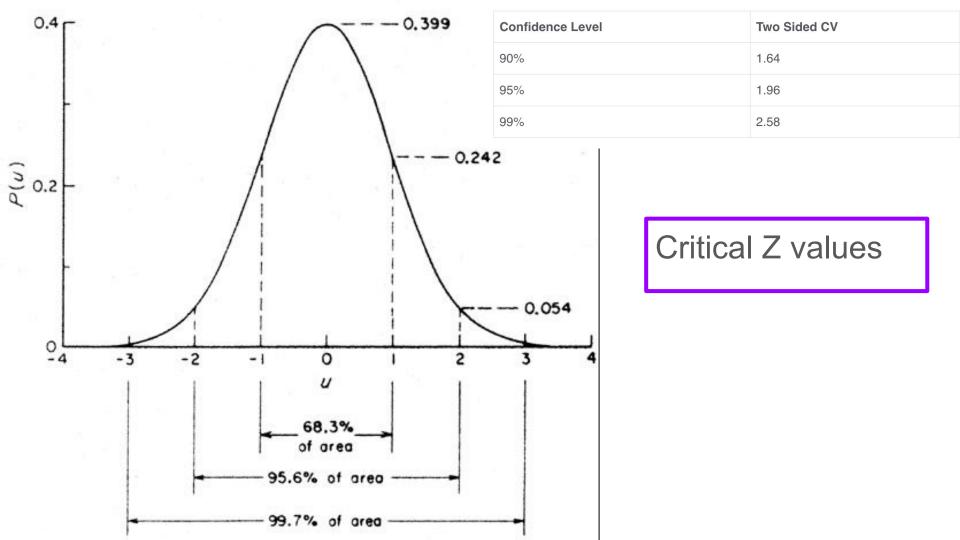

If we only measure the weight of 10 people, but we want to report a number range for which we are 95% sure to include the REAL population mean for weight...

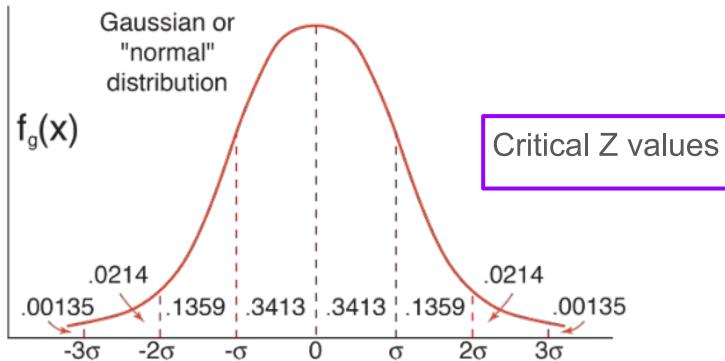

- confidence interval \rightarrow 95 % confidence interval = $100 \times (1 \alpha)$
- alpha = 0.05
- alpha / 2 = 0.025
- actual range given by:
 - o s is observed standard dev
 - o n is number of observations
 - o Critical Z value → 1.96

$$\bar{x} \pm z_{\alpha/2} \left(\frac{s}{\sqrt{n}} \right)$$

Nb. Critical Z is related to the concept of z-scored data $z = \frac{x_i - \bar{x}}{z}$

 measures data relative to mean and SD

-36 -26 -6 0 6 26 36		
Confidence Level	Two Sided CV	One Sided CV
90%	1.64	1.28
95%	1.96	1.65
99%	2.58	2.33

Fun way to find critical Z

- use numpy to make data that is drawn from a proper gaussian distribution
- find the value of the 97.5 percentile!

```
#% Calculate Critcal Z
alpha = 0.05
# Make gaussian data
mu, sigma = 0, 1 # sample mean and SEM
normdata = np.random.normal(mu, sigma, 10000000)
print(np.quantile(normdata, 1 - alpha/2))
```

Hypothesis Testing

Saying with some degree of certainty that a baseline hypothesis is true or false

- example, the weight of 100 shampoo bottles are observed...
 - o mean is 199.94g
 - o SD is 0.613
 - recall SD is square root of variance;
- baseline, or null hypothesis is that the sampling average weight is 200g
- problem: determine if the observed mean would reasonably be observed if the true mean were 200g
 - let the confidence level be set to 95%
 - Critical Z for 95% percent confidence is ±1.96
 - Use the observed mean to compute the standardized test statistic
 - If T is within the bounds we choose, the baseline null hypothesis stands!

$$T = \frac{\bar{x} - \mu_0}{s / \sqrt{n}}$$

Hypothesis Testing

$$T = \frac{\bar{x} - \mu_0}{s / \sqrt{n}}$$

Saying with some degree of certainty that a baseline hypothesis is true or false

- example, the weight of 100 shampoo bottles are observed...
 - o mean is 199.94g
 - o SD is 0.613
 - recall SD is square root of variance;
- baseline, or null hypothesis is that the sampling average weight is 200g
- problem: determine if the observed mean would reasonably be observed if the true mean were 200g
 - let the confidence level be set to 95%
 - Critical Z for 95% percent confidence is ±1.96
 - Use the observed mean to compute the standardized test statistic
 - If T is within the bounds we choose, the baseline null hypothesis stands!

$$T = (199.94 - 200) / (0.613 / 10)$$

$$T = -0.979$$

$$CI = \pm 1.96$$

T is within the CI, therefore the baseline hypothesis is not rejected!

The observed data do not disprove the hypothesis that 200g is the true weight of a shampoo bottle.
